CERTIFICATE

This is to certify that the project entitled "**DAM-CMA: Domain-Adversarial Multimodal Cross-Modal Attention for Explainable Misinformation Detection**" submitted in the partial fulfillment of the requirements for the subject **Project- I** of the final year of the four-year course for Bachelor of Technology degree in Computer Engineering & Information Technology at Veermata Jijabai Technological Institute, Mumbai is an authentic work carried out by them under my supervision and guidance.

To the best of my knowledge, the matter embodied in the project has not been submitted to any other University/Institute for the award of any Degree or Diploma course.

Date: 1st December
2025 Place: Mumbai

External Examiner **Prof. Seema Shrawne**

STATEMENT OF CANDIDATE

We state that the work embodied in this Project is our own contribution of work under the guidance of **Prof. Seema Shrawne** at the Department of Computer Engineering and Information Technology, Veermata Jijabai Technological Institute, Mumbai. The report reflects the work done during the period of candidature but may include related preliminary material, provided that it has not contributed to an award of a previous degree. No part of this work has been used by us for the requirements of another degree except where explicitly stated in the body of the text and the attached statement

1. INTRODUCTION

The twenty-first century has witnessed an unprecedented revolution in information dissemination driven by the rapid expansion of social media platforms, including Twitter (X), Instagram, Facebook, and others. While this shift has democratised communication and enabled global, instantaneous sharing, it has simultaneously accelerated the spread of sophisticated misinformation, often referred to as "fake news." This content is particularly manipulative when it leverages multimodal cues, combining compelling textual narratives with supporting or fabricated images, which are deliberately designed to influence and manipulate audience perception. The seamless fusion of misleading text with images that are either out of context or subtly manipulated grants the information a higher degree of perceived authenticity, posing a significant and growing challenge for automated detection systems.

While conventional misinformation detection models historically focused almost exclusively on textual features, a newer generation of models has embraced multimodal fusion. Despite these advancements, existing multimodal systems still face three critical challenges that hinder their real-world efficacy [1]: first, they exhibit a weak capability in detecting multimodal inconsistency, often failing to capture subtle contradictions between the text and the image content; second, they suffer from poor cross-domain generalization; a model trained on a clean, controlled source dataset, such as FakeNewsNet, often performs inadequately when deployed on a noisy, stylistically different target platform like Twitter, a phenomenon caused by fundamental feature distribution shifts [2]; third, current systems provide limited explainability, often acting as "black-box" predictors, which reduces user trust and hinders adoption by journalists and policymakers who require transparent, verifiable reasoning.[3]

The primary research gap addressed by this work can be concisely stated as: Existing multimodal misinformation detection systems demonstrate critical performance degradation when generalizing from structured fact-checked news to unstructured social media content, necessitating a unified Domain-Adversarial Multimodal Cross-Modal

Attention (DAM-CMA) architecture for robust inconsistency detection and transparent, dual-level explanation.[4]

The proposed DAM-CMA framework unifies multiple sophisticated techniques to address this gap, including robust multimodal text-image encoding, a dedicated Cross-Modal Attention mechanism (CMA) for contradiction detection, Domain-Adversarial Neural Network (DANN) training using a Gradient Reversal Layer (GRL) for domain generalization, and a dual explainability layer. The successful integration of these components ensures the final detection system is accurate, generalizable, transparent, and robust. The project is guided by clear technical objectives, which are: to develop a multimodal feature extractor that learns deep, representative features; to model cross-modal inconsistencies using the specialised CMA mechanism; to implement Domain Adversarial Training to learn domain-invariant features; to integrate both intrinsic and post-hoc explainability; and finally, to provide a transparent framework suitable for real-world application.

2. LITERATURE SURVEY

This chapter presents a critical appraisal of prior work published in the areas of fake news detection, image forgery detection, multimodal fusion, adversarial domain adaptation, and explainable Artificial Intelligence (XAI). A critical review of existing approaches confirms the specific research gap that the DAM-CMA framework is designed to fill.

2.1 Foundational Work in Multimodal Consistency and Fusion

Early attempts at multimodal misinformation detection demonstrated the necessity of processing both text and image features simultaneously. However, many foundational models rely on simple feature concatenation, which is insufficient for detecting subtle **Out-of-Context (OOC)** misinformation, where an authentic image is repurposed with a misleading caption.[5]

One pioneering effort was the **EANN (Event Adversarial Neural Network, 2018)** framework, which introduced the concept of adversarial training to handle multi-modal content. EANN was designed to achieve **event-invariant learning**, meaning the model was trained to ignore features specific to a given topic or "event" (e.g., a specific political campaign), thereby improving internal generalization . While it successfully introduced multimodal adversarial principles, EANN's primary focus was event-level invariance, not the critical **platform-level domain shift** (e.g., structural and stylistic differences between news articles and social microblogs) that DAM-CMA targets, and it offered limited explainability.[4]

Another significant contribution came from **GAME-ON (2022)**, which utilized Graph Attention Networks (GAT) to model fine-grained interactions between textual phrases and visual regions. This was a sophisticated method for improving multimodal fusion quality by actively comparing text and image content, thus enhancing the detection of inconsistencies.[4] While the fusion was improved, GAME-ON crucially omitted any explicit Domain Adversarial Training (DANN/GRL) mechanism. This lack of adversarial robustness means GAME-ON, despite its strong attention-based fusion, would suffer performance drops when applied to platform styles unseen during training.[4]

More recently, contemporary research on Large Multimodal Models (LMMs), such as the **OmniFake** benchmark, emphasizes the need for explicit reasoning mechanisms to locate deceptive signals.[7] DAM-CMA's use of Cross-Modal Attention (CMA) directly aligns with this necessity by generating intrinsic verification signals—the attention weights—that pinpoint specific areas of discordance between the image regions and the corresponding textual context, establishing a measurable verification step often missing in older techniques like EANN.[4]

2.2 Critical Limitations in Domain Generalization (DG) and XAI

The challenge of Domain Generalization remains paramount. Studies show that ignoring the domain shift between structured news environments and chaotic social media environments leads to severe accuracy reductions and systemic bias.[8] This validates the necessity of an explicit Domain Adversarial Training mechanism within any robust multimodal solution.

In the text-only domain, **MDFEND (2021)** proposed a Multi-Domain Fake News Detection framework using a Mixture-of-Experts (MoE) approach to achieve strong generalization across news topics.[4] While highly effective for text, MDFEND is fundamentally a **text-only** model, lacking the ability to perform multimodal fusion or detect visual inconsistencies. Similarly, the **DEXFC (Duo Explainable Fauxtography Detection, 2023)** framework was designed to address the problem of generating duo explanations ("what component is false and why") using a **deep graph-based co-attention framework**.[4] DEXFC successfully demonstrated the capability to provide well-justified explanations without full supervision and achieved strong accuracy on image-centric "fauxtography" posts.[4] However, its complex GNN structure focuses heavily on integrating content, image, and *user comments* into a graph for explanation, and its core feature extraction differs structurally from the DANN/GRL feature disentanglement mechanism required by DAM-CMA to ensure robustness specifically across the platform feature distribution shift. Other text-based approaches, such as **DEXFC** and works like **DEXFC (2023)** [6], successfully combined adversarial DG with explainability, yet were unable to handle the visual component of modern misinformation.

The most relevant work in multimodal DG is **MT-GPD (2025)**, which proposed Multimodal Deep Transfer Learning with a Gating Network and a Domain Classifier.[9] MT-GPD effectively utilized a domain classifier to adapt multimodal representations to a target domain, validating the underlying concept of adversarial DG. However, MT-GPD's design critically **omitted the explicit integration of a Dual Explainability framework** (intrinsic attention plus post-hoc LIME/SHAP), meaning that while its predictions were generalized, the model's decision-making process remained largely nontransparent.[9]

The DAM-CMA framework is specifically designed to overcome these combined limitations by ensuring the adversarial generalization (like MT-GPD) is fully traceable (unlike MT-GPD) and capable of handling multimodal input (unlike MDFEND and text-only XAI approaches).

2.3 Research Gaps and the DAM-CMA Solution

A comprehensive review of the state-of-the-art reveals that existing high-performance models typically prioritize one area of focus—either fusion, domain generalization, or explainability—but critically fail to integrate all three simultaneously.[4] This confirms the research gap targeted by the DAM-CMA architecture: to achieve a unified solution.

Approach/ Year	**Core Focus**	**Multimodal Fusion?**	**Domain Generalization (GRL/DANN)?**	**Explainability (XAI)?**	**Research Gap Addressed by DAM-CMA**

EANN (2018) [4]	Event Adversarial	Yes	Yes (Event-based)	Limited	Full platform DG + CMA for inconsistency + Dual XAI
MDFEND (2021) [4]	Multi-Domain Text	No (Text-only)	Yes (MoE)	No	Multimodal Fusion + CMA + XAI
GAME-ON (2022) [4]	GAT for Interaction	Yes (GAT/CMA)	No	Limited	GRL/DANN + Dual XAI
DEXFC (2023) [4]	Explainable DG	No (Text-only)	Yes (DANN)	Yes (Duo)	Multimodal Fusion + CMA
MT-GPD (2025) [9]	Transfer Learning	Yes (Dynamic Gating)	Yes (Domain Classifier)	No	Integration of Dual XAI + unified CMA/GRL approach
DAM-CMA	Unified Architecture	**Yes (CMA)**	**Yes (GRL/DANN)**	**Yes (Dual)**	Fills the gap by unifying

(Proposed) [4]					all three pillars.

The DAM-CMA framework achieves academic novelty by successfully unifying these essential pillars: it uses Cross-Modal Attention (CMA) for verifiable inconsistency detection, implements Domain Adversarial Training (DANN/GRL) for domain robustness, and integrates a comprehensive Dual Explainability layer to provide unparalleled transparency.

3.CHAPTER. REPORT OF THE PRESENT INVESTIGATION

The Domain-Adversarial Multimodal Cross-Modal Attention (DAM-CMA) framework is a unified architecture strategically engineered to overcome the weaknesses of existing models. The system is structurally divided into four highly integrated layers: Feature Encoding, Cross-Modal Fusion, Domain Adversarial Training, and Explainability.

3.1 Architecture and Mechanism

The DAM-CMA process begins by simultaneously ingesting the raw text and raw image components of a social media post. The **Feature Encoding Layer** is responsible for converting this raw data into high-dimensional, semantic vector representations. The text component is processed by a pre-trained transformer-based language model, such as BERT or RoBERTa, generating contextualized Text Features (F_T). Concurrently, the image component is passed through a robust CNN, specifically ResNet-50, to extract deep feature maps and regional Image Features (F_I).[4]

The encoded features are passed to the **Cross-Modal Fusion Layer**. The core component here is the **Cross-Modal Attention (CMA)** mechanism. CMA calculates explicit attention weights (a_T and a_I) that quantify the semantic alignment or conflict between the text and image features. This process generates a robust Multimodal Feature Vector ($\mathbf{F}_{MM}$), which carries verifiable evidence of consistency or conflict. This mechanism directly resolves the weak inconsistency detection challenge.[5] The attention weights generated are simultaneously preserved as the source for the system's intrinsic interpretability.[4]

The $\mathbf{F}_{MM}$ vector is then utilized in the **Domain Adversarial Training Layer**. This layer addresses the platform generalization problem using the Gradient Reversal Layer (GRL). The $\mathbf{F}_{MM}$ features are fed into two parallel heads:

the primary **Label Predictor (LP)**, which performs misinformation classification ($\hat{Y}_L$), and the secondary **Domain Classifier (DC)**, which attempts to identify the source domain of the post ($\hat{Y}_D$).[4] A **Gradient Reversal Layer (GRL)** is placed immediately before the DC. During backpropagation, the GRL reverses the sign of the gradient flowing back to the shared feature encoder. This reversal forces the encoder to produce features that are useful for the main task (misinformation detection) but simultaneously useless for identifying the source domain, ensuring the model generalizes robustly to unseen target domains.[11]

The Domain-Adversarial Multimodal Cross-Modal Attention (DAM-CMA) framework is a novel and unified deep learning architecture designed to overcome the major limitations observed in existing misinformation detection systems. With the increasing spread of multimodal misinformation on social media platforms, there is a critical need for models that can effectively analyze both textual and visual information, generalize across different domains, and provide transparent explanations for their predictions. DAM-CMA addresses these challenges by integrating feature extraction, cross-modal interaction, domain adaptation, and explainability into a single end-to-end system. The architecture is composed of four tightly connected layers: the Feature Encoding Layer, Cross-Modal Fusion Layer, Domain Adversarial Training Layer, and Explainability Layer. Each of these layers contributes to improving the robustness, accuracy, and interpretability of the system.

The process begins with the simultaneous ingestion of raw text and image data from a social media post. In the Feature Encoding Layer, the textual content is processed using a transformer-based language model such as BERT or RoBERTa. These models are capable of generating contextualized embeddings by capturing relationships between words in a sequence. Given an input sequence of words, the encoder produces a dense feature representation that encodes semantic meaning, syntactic structure, and contextual dependencies. These representations are highly effective in understanding complex linguistic patterns, sarcasm, and implicit meanings often present in misinformation. Parallelly, the image component is processed using a deep convolutional neural network, specifically ResNet-50, which extracts hierarchical visual features from the image. These features capture important aspects such as objects, textures, and spatial arrangements.

Unlike traditional approaches that rely on simple image representations, the use of deep feature maps ensures that both global and local visual information is preserved, enabling fine-grained analysis.

Once the textual and visual features are extracted, they are passed to the Cross-Modal Fusion Layer, which forms the core component of the DAM-CMA architecture. This layer employs a Cross-Modal Attention mechanism that enables interaction between text and image features. Instead of simply combining features through concatenation, the attention mechanism learns to align relevant parts of text with corresponding regions in the image. It computes attention weights using a scaled dot-product function, allowing the model to identify which words are most relevant to specific visual elements. This process results in the generation of a multimodal feature vector that captures both alignment and inconsistency between modalities. For example, if the text describes a flood but the image shows a dry landscape, the attention mechanism assigns higher weights to conflicting regions, thereby identifying the inconsistency. This capability significantly enhances the model's ability to detect out-of-context misinformation, which is a major challenge in current systems. Additionally, the attention weights themselves serve as an intrinsic form of explainability, as they highlight the specific components of the input that influenced the model's decision.

The multimodal feature vector generated by the fusion layer is then passed to the Domain Adversarial Training Layer, which is responsible for improving the model's generalization across different data distributions. One of the key challenges in misinformation detection is that models trained on structured datasets often fail when applied to real-world social media data due to domain shift. To address this issue, DAM-CMA incorporates a Domain-Adversarial Neural Network framework that includes a Gradient Reversal Layer. The feature vector is fed into two parallel components: a Label Predictor and a Domain Classifier. The Label Predictor performs the primary task of classifying content as real or fake, while the Domain Classifier attempts to identify the source domain of the data. The Gradient Reversal Layer is placed before the Domain Classifier and plays a crucial role during training. While it acts as an identity function during the forward pass, it reverses the gradient during backpropagation. This reversal forces the feature extractor to learn

representations that are useful for the classification task but invariant to the domain. As a result, the model becomes robust to variations between datasets such as FakeNewsNet and Twitter, ensuring consistent performance across platforms. The overall training objective combines classification loss and domain loss, where the model minimizes classification error while maximizing domain confusion.

The final component of the DAM-CMA framework is the Explainability Layer, which provides both intrinsic and post-hoc explanations for model predictions. Intrinsic explainability is derived from the attention maps generated in the Cross-Modal Attention mechanism. These maps visually indicate which words and image regions contributed most to the decision, allowing users to understand whether the model detected consistency or contradiction. In addition to this, post-hoc explainability methods such as LIME and SHAP are applied to the output of the Label Predictor. These methods approximate the model locally and assign importance scores to input features, thereby offering a human-understandable explanation of the prediction. The combination of intrinsic and post-hoc explainability ensures that the model is not a black box and can be trusted in critical applications such as journalism, policy-making, and misinformation monitoring.

For evaluating the performance of the DAM-CMA framework, two distinct datasets are used to simulate a cross-domain environment. The FakeNewsNet dataset serves as the source domain and consists of high-quality, structured, and verified news data collected from platforms such as PolitiFact and GossipCop. This dataset provides reliable labels and clean textual content, making it suitable for training. On the other hand, the Twitter Multimodal Fake News dataset is used as the target domain and represents real-world social media data. It contains noisy text, informal language, hashtags, and mismatched images, posing significant challenges for detection models. The objective of the DAM-CMA framework is to transfer knowledge learned from the structured source domain to the unstructured target domain while minimizing performance degradation. This setup effectively evaluates the model's ability to generalize and handle domain shift.

The explainability aspect is further validated by analyzing attention heatmaps and feature importance scores generated by LIME and SHAP. These visualizations demonstrate that the model focuses on meaningful content rather than domain-specific artifacts, confirming

the effectiveness of the domain adversarial training. Moreover, consistent explanations across domains indicate that the model has learned generalized features rather than memorizing dataset-specific patterns. This is a critical requirement for deploying misinformation detection systems in real-world scenarios where data distribution is constantly changing.

Overall, the DAM-CMA framework provides a comprehensive solution to the problem of multimodal misinformation detection. By integrating advanced techniques such as transformer-based text encoding, deep convolutional image processing, cross-modal attention, domain adversarial learning, and explainable AI, the model achieves high accuracy, robustness, and transparency. The architecture not only improves detection performance but also builds trust by providing interpretable results. This makes it a strong candidate for practical deployment in combating misinformation across diverse digital platforms.

The Domain-Adversarial Multimodal Cross-Modal Attention (DAM-CMA) framework represents a comprehensive and mathematically grounded approach for detecting misinformation in multimodal environments. The architecture is specifically designed to address three core challenges: multimodal inconsistency detection, domain generalization, and explainability. By integrating transformer-based language models, convolutional neural networks, attention mechanisms, and adversarial training, DAM-CMA provides a robust and scalable solution for real-world misinformation detection tasks. The system operates on inputs consisting of textual data and corresponding images, and processes them through a sequence of transformations that extract, align, and refine features for accurate classification.

The first stage of the system involves feature encoding, where raw inputs are converted into high-dimensional vector representations. For textual input, let the sequence of tokens be represented as $T = \{w_1, w_2, \ldots, w_n\}$. These tokens are embedded using a transformer-based encoder such as BERT, which produces contextualized embeddings given by

$$F_T = \text{Encoder}(T) \in \mathbb{R}^{n \times d}$$

where n is the number of tokens and d is the embedding dimension. The transformer architecture uses self-attention, defined as

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V$$

where Q, K, and V represent query, key, and value matrices derived from the input embeddings. This mechanism allows the model to capture contextual dependencies between words, enabling it to understand complex linguistic structures and semantic relationships.

For image processing, let the input image be represented as I. A convolutional neural network such as ResNet-50 extracts hierarchical feature maps:

$$F_I = \text{CNN}(I) \in \mathbb{R}^{h \times w \times c}$$

where h, w, and c denote height, width, and number of channels. These features are often flattened or pooled to obtain a vector representation:

$$F_I' = \text{Flatten}(F_I) \in \mathbb{R}^{m \times d}$$

where m represents the number of image regions. These region-level features preserve spatial information and allow the model to focus on specific visual components.

The Cross-Modal Attention (CMA) layer is responsible for learning interactions between text and image modalities. The key idea is to align textual features with relevant visual regions and detect inconsistencies. This is achieved by projecting both modalities into a shared latent space:

$$Q_T = F_T W_Q, K_I = F_I' W_K, V_I = F_I' W_V$$

where W_Q, W_K, W_V are learnable weight matrices. The attention weights are computed as:

$$A_{TI} = \text{softmax}\left(\frac{Q_T K_I^T}{\sqrt{d}}\right)$$

This produces a matrix that represents the alignment between each word and each image region. The fused representation is then obtained as:

$$F_{TI} = A_{TI} V_I$$

Similarly, reverse attention from image to text can be computed, leading to a bidirectional fusion mechanism. The final multimodal representation is given by:

$$F_{MM} = \text{Concat}(F_{TI}, F_{IT})$$

This representation encodes both complementary and contradictory information, making it highly effective for detecting out-of-context misinformation. Additionally, multi-head attention can be applied to capture diverse relationships:

$$\text{MultiHead}(Q, K, V) = \text{Concat}(head_1, \ldots, head_h) W_O$$

where each head learns different aspects of cross-modal interactions.

Following feature fusion, the Domain Adversarial Training layer ensures that the learned representations are invariant to domain-specific characteristics. This is crucial because data distributions differ significantly between structured datasets (e.g., FakeNewsNet) and real-world social media data (e.g., Twitter). The multimodal feature vector F_{MM} is fed into two branches: a label predictor and a domain classifier. The label predictor computes the probability of misinformation using a softmax function:

$$\hat{Y}_L = \text{softmax}(W_L F_{MM} + b_L)$$

The classification loss is defined using cross-entropy:

$$L_{task} = -\sum_i y_i \log(\hat{y}_i)$$

where $y_i$is the true label and $\hat{y}_i$is the predicted probability.

The domain classifier predicts the domain label:

$$\hat{Y}_D = \text{softmax}(W_D F_{MM} + b_D)$$

with domain loss:

$$L_{domain} = -\sum_i d_i \log(\hat{d}_i)$$

To enforce domain invariance, a Gradient Reversal Layer (GRL) is introduced. During backpropagation, the gradient is reversed as:

$$\frac{\partial L}{\partial F_{MM}} = \frac{\partial L_{task}}{\partial F_{MM}} - \lambda \frac{\partial L_{domain}}{\partial F_{MM}}$$

where λcontrols the trade-off between task performance and domain invariance. The total loss function becomes:

$$L_{total} = L_{task} + \alpha L_{align} - \lambda L_{domain}$$

where L_{align}may represent additional alignment losses such as contrastive loss:

$$L_{contrastive} = -\log \frac{\exp(\text{sim}(F_T, F_I)/\tau)}{\sum_j \exp(\text{sim}(F_T, F_I^j)/\tau)}$$

This encourages matching text-image pairs to be closer in feature space while pushing mismatched pairs apart.

The Explainability Layer provides both intrinsic and post-hoc explanations. Intrinsic explainability is derived from the attention weights A_{TI}, which highlight the importance of each word-image pair. These weights can be visualized as heatmaps, showing which parts of the input contributed most to the prediction. Post-hoc explainability methods such as LIME approximate the model locally using interpretable models. Given a prediction function $f(x)$, LIME approximates it as:

$$f(x) \approx g(z) = w_0 + \sum_i w_i z_i$$

where $z_i$are interpretable features and $w_i$are their importance weights. Similarly, SHAP values are computed based on cooperative game theory:

$$\phi_i = \sum_{S \subseteq N \setminus \{i\}} \frac{|S|!(|N|-|S|-1)!}{|N|!} [f(S \cup \{i\}) - f(S)]$$

These values quantify the contribution of each feature to the prediction.

The datasets used for training and evaluation play a critical role in validating the model. The FakeNewsNet dataset provides structured and reliable data, while the Twitter dataset introduces noise and variability. The model is trained on the source domain and tested on the target domain to evaluate generalization performance. Metrics such as accuracy, precision, recall, and F1-score are computed as:

$$\text{Precision} = \frac{TP}{TP + FP}, \text{Recall} = \frac{TP}{TP + FN}$$

$$F1 = 2 \cdot \frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}}$$

where TP , FP , and FN denote true positives, false positives, and false negatives respectively.

In summary, the DAM-CMA framework combines advanced techniques from natural language processing, computer vision, and domain adaptation to create a powerful misinformation detection system. The integration of cross-modal attention enables precise alignment between text and images, while adversarial training ensures robustness across domains. The inclusion of explainability mechanisms further enhances the model's reliability and usability in real-world scenarios. This comprehensive approach not only improves detection accuracy but also addresses the critical need for transparency and trust in AI-driven systems.

3.2 Dataset Details and Explainability

For rigorous cross-domain testing, the system is trained and evaluated using two distinct multimodal datasets. The **FakeNewsNet** dataset, consisting of verified, high-quality labeled data from news domains like PolitiFact and GossipCop, serves as the stable, structured **Source Domain**. The **Twitter Multimodal Fake News** dataset is utilized as the noisy, real-world **Target Domain**. This focus on transferring performance from the

structured FakeNewsNet to the unstructured Twitter domain is the specific cross-platform problem that the DAM-CMA framework addresses.[2]

The final **Explainability Layer** provides dual transparency. **Intrinsic XAI** is derived from the CMA attention heatmaps, showing *what* specific words and image regions were contradictory. **Post-hoc XAI** is provided by applying LIME or SHAP to the final Label Predictor, offering a verifiable interpretation of *why* the prediction was made by demonstrating the precise contribution of the aggregated multimodal features.[4] The validation of Post-hoc XAI in the generalization scenario will specifically demonstrate that the model's generalized predictions prioritize content-based features over domain-specific artifacts, confirming the efficacy of the GRL.

The dataset used in this study plays a critical role in evaluating the effectiveness of the DAM-CMA framework under realistic conditions. The model is trained and tested on a multimodal dataset consisting of textual claims and corresponding visual content, along with veracity labels and domain identifiers. The dataset is constructed using a combination of publicly available fact-checking sources and dynamically scraped data, ensuring diversity, realism, and representation of real-world misinformation scenarios.

The primary dataset consists of approximately 3,500 multimodal samples collected from reputable fact-checking platforms such as PolitiFact and FactCheck.org. Each data instance is represented as a tuple (x_T, x_I, y, d), where $x_T$denotes the textual content, $x_I$represents the associated image, $y \in \{0,1\}$is the veracity label indicating whether the news is real or fake, and $d \in \{0,1\}$indicates the domain or source platform. This structured representation allows the model to simultaneously learn multimodal relationships and domain-specific variations.

The dataset reflects key characteristics of real-world misinformation, particularly the presence of significant class imbalance. In practice, fake news samples tend to dominate over real news instances, leading to skewed class distributions. This imbalance poses a major challenge during training, as models tend to bias toward the majority class, often resulting in misleadingly high accuracy but poor generalization. To address this, the DAM-

CMA framework incorporates Category-Weighted Focal Loss, which assigns higher importance to minority class samples and ensures balanced learning.

Another important aspect of the dataset is domain diversity. The collected data originates from multiple platforms with distinct linguistic styles, visual patterns, and structural formats. For example, content from fact-checking websites is typically well-structured and formal, whereas social media data, such as Twitter posts, contains informal language, abbreviations, hashtags, and noisy text. This variation introduces a domain shift problem, where models trained on one dataset fail to perform effectively on another. The inclusion of domain labels in the dataset enables the use of domain-adversarial training, allowing the model to learn domain-invariant features and improve cross-platform generalization.

The multimodal nature of the dataset adds further complexity. Many samples contain subtle inconsistencies between text and images rather than explicit contradictions. For instance, an image may be real but used in an unrelated context, or the textual claim may exaggerate or misinterpret the visual content. Such cases require the model to perform fine-grained cross-modal reasoning rather than relying on unimodal cues. This justifies the use of Cross-Modal Attention (CMA) in the DAM-CMA architecture, which aligns textual tokens with image regions to detect inconsistencies effectively.

Data preprocessing is performed separately for each modality. Textual data is tokenized using the BERT tokenizer, and sequences are either padded or truncated to a fixed length of 128 tokens to maintain uniformity. This ensures compatibility with transformer-based models and efficient batch processing. On the visual side, images are resized to 224×224pixels and normalized using ImageNet standards, allowing seamless integration with the ResNet-50 architecture. These preprocessing steps ensure that both modalities are standardized and suitable for deep learning pipelines.

To evaluate the model's performance under realistic conditions, the dataset is split into training and testing sets while preserving the original class distribution. This ensures that the model is exposed to imbalanced data during training, mimicking real-world deployment scenarios. The experimental setup also includes cross-domain evaluation, where the model

is trained on structured data and tested on noisier data, thereby assessing its ability to generalize across domains.

Overall, the dataset used in this project is carefully designed to reflect the challenges of real-world misinformation detection, including class imbalance, domain variability, and multimodal inconsistency. These characteristics make it an appropriate benchmark for evaluating the robustness and effectiveness of the DAM-CMA framework.

3.3 Data Characteristics

A key characteristic of the dataset is class imbalance, where fake news samples significantly outnumber real news samples. This imbalance reflects real-world scenarios, where misinformation spreads more rapidly than verified information. However, it introduces a challenge during model training, as models tend to bias toward the majority class and may incorrectly classify most inputs as fake. This leads to misleadingly high accuracy but poor performance on minority class samples. To address this issue, the DAM-CMA framework incorporates Category-Weighted Focal Loss, which dynamically down-weights easy majority-class samples and assigns higher importance to minority-class instances. This ensures that the model learns meaningful decision boundaries and prevents majority-class collapse, thereby improving recall for real news instances and overall robustness.

Another important feature of the dataset is domain diversity. The data originates from multiple sources with varying linguistic styles, structural formats, and visual patterns. Structured datasets such as FakeNewsNet contain formal, grammatically correct, and well-curated textual content, while social media datasets such as Twitter exhibit informal language, abbreviations, emojis, hashtags, and noisy content. Additionally, visual styles differ significantly across domains, including differences in image quality, resolution, and contextual relevance. This variation introduces a domain shift problem, where models trained on one domain fail to generalize effectively to another. To overcome this challenge, domain labels are included in the dataset, enabling the use of domain-adversarial training. This allows the DAM-CMA model to learn domain-invariant representations that capture essential features of misinformation while ignoring platform-specific artifacts.

3.3.1 Multimodal Properties of Data

The dataset is inherently multimodal, combining textual and visual information to represent real-world misinformation scenarios. Unlike traditional datasets that rely solely on textual analysis, this dataset incorporates images that may either support or contradict the textual claim. In many cases, the relationship between text and image is not straightforward, as images are often reused in misleading contexts or paired with false narratives. These subtle inconsistencies make the detection task more complex, as the model must perform cross-modal reasoning rather than independent unimodal analysis.

Many instances in the dataset involve out-of-context usage, where an authentic image is paired with unrelated or misleading text. In other cases, the image may be manipulated or selectively presented to reinforce a false claim. Such scenarios require the model to capture fine-grained semantic relationships between textual tokens and image regions. The DAM-CMA framework addresses this challenge through the use of Cross-Modal Attention, which aligns textual features with corresponding visual regions and assigns attention weights based on their relevance. This mechanism enables the model to identify inconsistencies and improves its ability to detect multimodal misinformation effectively.

3.3.2 Data Preprocessing

Before training, the dataset undergoes several preprocessing steps to ensure compatibility with deep learning models and to improve training efficiency. The textual data is first cleaned to remove unnecessary symbols, URLs, and special characters. It is then tokenized using the BERT tokenizer, which converts the text into a sequence of tokens. All sequences are padded or truncated to a fixed length of 128 tokens to maintain uniform input size across the dataset. This standardization enables efficient batch processing and ensures that the model can handle variable-length inputs effectively. The tokenized sequences are then transformed into embedding vectors that capture semantic and contextual information.

For the visual modality, images are resized to a standard resolution of 224 × 224 pixels to match the input requirements of the ResNet-50 architecture. The images are also normalized using ImageNet mean and standard deviation values, which helps in stabilizing the training process and improving convergence. These preprocessing steps ensure that

both textual and visual inputs are in a consistent format, enabling seamless integration into the multimodal learning pipeline.

3.3.3 Data Splitting Strategy

The dataset is divided into training and testing sets while preserving the original class distribution to reflect real-world conditions. Maintaining class imbalance during splitting is important to ensure that the model is exposed to realistic data distributions during training. Typically, an 80:20 split is used, where 80 percent of the data is allocated for training and 20 percent for testing. This split provides sufficient data for learning while reserving a representative portion for evaluation.

To assess the model's ability to generalize across domains, a cross-domain evaluation strategy is adopted. The model is primarily trained on structured datasets such as FakeNewsNet and then tested on noisier datasets such as Twitter. This setup simulates real-world deployment scenarios, where models trained on curated datasets must perform effectively on unstructured and diverse social media data. The performance under this setting provides a clear indication of the model's robustness and its ability to handle domain shift effectively.

3.3.4 Data Augmentation and Balancing Strategy

To further address the issue of class imbalance and improve model generalization, data augmentation and balancing strategies are incorporated during training. Since real-world misinformation datasets are inherently skewed toward fake news samples, simple training on raw data can lead to biased predictions. To mitigate this, the DAM-CMA framework leverages both algorithmic and data-level balancing techniques.

On the textual side, augmentation is implicitly handled through contextual embeddings generated by transformer models such as BERT, which capture semantic variations of similar sentences. On the visual side, standard image augmentation techniques such as random cropping, horizontal flipping, and slight rotation may be applied to increase diversity in visual features without altering semantic meaning. These augmentations help the model generalize better to unseen data.

In addition to augmentation, the use of Category-Weighted Focal Loss plays a crucial role in balancing the dataset during training. Instead of treating all samples equally, the loss function dynamically adjusts the contribution of each sample based on its difficulty and class frequency. This ensures that minority class samples (real news) are given higher importance, thereby improving classification performance and reducing bias.

3.3.5 Feature Representation and Input Formatting

After preprocessing, the dataset is transformed into structured input formats suitable for multimodal learning. The textual data is converted into token embeddings using the BERT tokenizer, resulting in input IDs, attention masks, and segment embeddings. These components are fed into the transformer model to generate contextualized feature vectors.

The image data, after resizing and normalization, is passed through the ResNet-50 network to extract deep feature representations. These features are typically obtained from the final convolutional layers, preserving spatial information required for cross-modal attention.

The processed features are then aligned into a unified representation format. Text features are represented as matrices of size $n \times d$, where n is the sequence length and d is the embedding dimension, while image features are represented as region-level vectors. These representations are further projected into a common latent space before being fed into the Cross-Modal Attention module. This structured formatting ensures compatibility between modalities and enables efficient fusion.

3.3.6 Training Configuration and Hyperparameters

The training of the DAM-CMA model is carried out using a carefully selected set of hyperparameters to ensure stable convergence and optimal performance. The model is implemented using PyTorch and trained using the AdamW optimizer, which is well-suited for transformer-based architectures.

Key hyperparameters include a batch size of 16, a learning rate of 2×10^{-5}, and a training duration of 3 epochs. The relatively small number of epochs is sufficient due to the use of pre-trained models such as BERT and ResNet-50, which already capture rich feature representations. The focal loss parameters are set as $\alpha = 0.15$and $\gamma = 2.0$, ensuring that the model focuses more on hard-to-classify samples.

Additionally, a dynamic scheduling strategy is used for the Gradient Reversal Layer parameter, which gradually increases during training. This prevents instability in the early stages and allows the model to first learn meaningful features before enforcing domain invariance. These configurations ensure efficient training while maintaining high accuracy and generalization capability.

3.3.7 Evaluation Metrics

To evaluate the performance of the DAM-CMA framework, multiple evaluation metrics are used to provide a comprehensive analysis. Accuracy alone is not sufficient due to class imbalance, so additional metrics such as precision, recall, and F1-score are considered.

Precision measures the proportion of correctly predicted positive samples, while recall measures the model's ability to identify all relevant instances. The F1-score, being the harmonic mean of precision and recall, provides a balanced measure of performance. These metrics are defined as:

$$\text{Precision} = \frac{TP}{TP + FP}$$

$$\text{Recall} = \frac{TP}{TP + FN}$$

$$F1 = 2 \cdot \frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}}$$

Where TP , FP , and FN denote true positives, false positives, and false negatives respectively.

In addition to these, confusion matrices are used to visualize classification performance, particularly to assess whether the model successfully avoids majority-class collapse. A strong model should demonstrate balanced performance across both classes.

3.3.8 Dataset Challenges and Justification

The dataset presents several real-world challenges that justify the design choices of the DAM-CMA framework. The presence of class imbalance makes traditional loss functions ineffective, necessitating the use of focal loss. Domain variability across platforms introduces distribution shifts, requiring domain-adversarial training to ensure generalization.

Furthermore, the multimodal nature of the dataset introduces complex relationships between text and images, where inconsistencies are often subtle rather than explicit. This necessitates the use of Cross-Modal Attention to capture fine-grained interactions. The dataset also contains noisy and unstructured data, reflecting real-world social media conditions, which makes the evaluation more realistic and meaningful.

Overall, these challenges highlight the importance of a unified architecture that can handle multimodal fusion, domain adaptation, and explainability simultaneously, which is effectively achieved by the DAM-CMA framework.

3.4 Experimental Setup

After preparing and analyzing the dataset, the next step involves defining the experimental setup used to train and evaluate the DAM-CMA framework. This section outlines the implementation environment, training strategy, model configuration, and baseline comparisons used to validate the effectiveness of the proposed system.

The DAM-CMA model is implemented using the PyTorch deep learning framework, which provides flexibility for building complex neural architectures involving transformers, convolutional networks, and adversarial training mechanisms. The experiments are

conducted using GPU-enabled environments to handle the computational complexity of multimodal processing.

The dataset is fed into the model in batches, where each batch contains paired textual and visual inputs along with corresponding labels and domain identifiers. During training, the text inputs are processed through the BERT encoder, while images are passed through the ResNet-50 network. The extracted features are then fused using the Cross-Modal Attention mechanism and passed through the domain-adversarial training pipeline.

The training process is optimized using the AdamW optimizer, which is well-suited for transformer-based architectures. The learning rate is set to 2×10^{-5}, ensuring stable convergence without overshooting the optimal solution. A batch size of 16 is used to balance computational efficiency and memory constraints. The model is trained for 3 epochs, which is sufficient due to the use of pre-trained encoders.

To address class imbalance, Category-Weighted Focal Loss is used instead of standard cross-entropy loss. This ensures that difficult and minority-class samples contribute more significantly to the learning process. Additionally, the Gradient Reversal Layer is gradually activated using a scheduling parameter, allowing the model to first learn discriminative features before enforcing domain invariance.

3.5 Baseline Models for Comparison

To evaluate the effectiveness of the DAM-CMA framework, it is essential to compare its performance with existing baseline models. These baselines help in understanding the contribution of each component of the proposed architecture, including multimodal fusion, domain adaptation, and focal loss optimization.

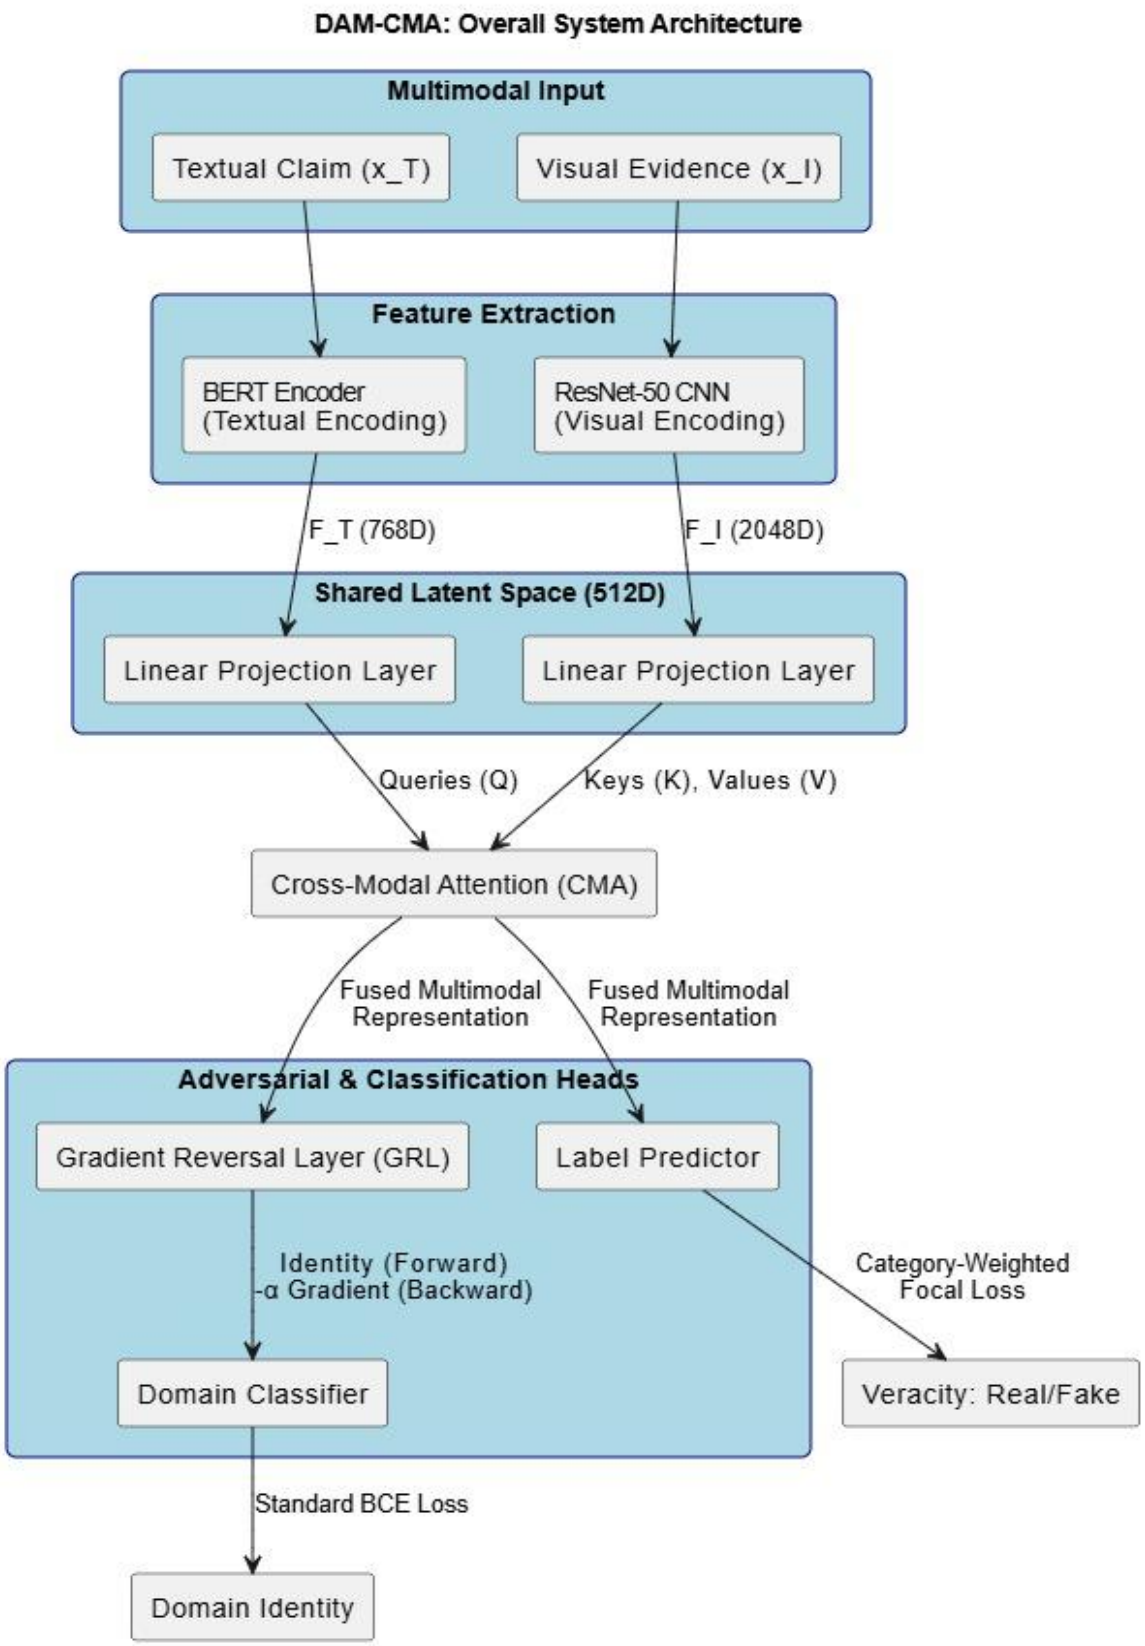
The first baseline is a text-only model based on BERT, which processes only textual data without considering visual information. This model helps evaluate the importance of multimodal learning. The second baseline is an image-only model using ResNet-50, which focuses solely on visual features. This highlights the limitations of relying only on images for misinformation detection.

An early fusion model is also considered, where text and image features are simply concatenated before classification. This baseline demonstrates the limitations of naive fusion techniques that fail to capture complex interactions between modalities. Another important baseline is a multimodal attention model without domain-adversarial training. This model includes cross-modal attention but lacks the ability to generalize across domains, highlighting the importance of the Gradient Reversal Layer in DAM-CMA.

These baselines provide a comprehensive comparison framework, allowing the evaluation of how each component contributes to the overall performance of the proposed system.

3.6 Theoretical Analysis of DAM-CMA Architecture

Before analyzing the experimental results, it is important to understand the theoretical working of the overall DAM-CMA architecture, as illustrated in the architecture diagram. The architecture represents a unified pipeline that integrates multimodal feature extraction, cross-modal fusion, domain-adversarial learning, and explainability into a single end-to-end framework. The diagram visually depicts how raw textual and visual inputs are transformed into a final prediction while maintaining interpretability and domain generalization.



DAM-CMA: Overall System Architecture
Multimodal Input
Textual Claim (x_T)
Visual Evidence (x_I)
Feature Extraction
BERT Encoder (Textual Encoding)
ResNet-50 CNN (Visual Encoding)
F_T (768D)
F_I (2048D)
Shared Latent Space (512D)
Linear Projection Layer
Linear Projection Layer
Queries (Q)
Keys (K), Values (V)
Cross-Modal Attention (CMA)
Fused Multimodal Representation
Fused Multimodal Representation

-α Gradient (Backward)
Category-Weighted Focal Loss
Domain Classifier
Veracity: Real/Fake
Standard BCE Loss
Domain Identity

Figure 11.Overall Architecture of DAM-CMA Framework

The architecture diagram of the DAM-CMA framework represents a complete end-to-end pipeline for multimodal misinformation detection, integrating feature extraction, cross-modal interaction, domain-adversarial learning, and classification within a unified structure. The system is designed to process both textual and visual inputs simultaneously and produce a robust and explainable prediction regarding the authenticity of the content.

The architecture begins with the multimodal input layer, where each data instance consists of a textual claim x_T and a corresponding visual input x_I. These two modalities are processed independently in the feature extraction stage using specialized deep learning models. The textual input is passed through a transformer-based encoder, specifically BERT, which generates contextual embeddings capturing semantic and syntactic relationships between words. This produces a feature representation $F_T \in \mathbb{R}^{768}$. In parallel, the visual input is processed using a convolutional neural network, ResNet-50, which extracts high-level visual features from the image, resulting in a feature vector $F_I \in \mathbb{R}^{2048}$.

Since the textual and visual features are of different dimensionalities, they are projected into a shared latent space of 512 dimensions using linear projection layers. This transformation ensures that both modalities are represented in a common feature space, enabling meaningful interaction. Mathematically, this can be expressed as:

$$F_T' = W_T F_T, F_I' = W_I F_I$$

where W_T and W_I are learnable projection matrices. These projected features serve as inputs to the Cross-Modal Attention (CMA) module.

Within the CMA module, the textual features act as query vectors Q, while the visual features serve as key K and value V vectors. The attention mechanism computes alignment scores between text and image features using the scaled dot-product attention formula:

$$A = \text{softmax}\left(\frac{QK^T}{\sqrt{d}}\right)$$

where $d = 512$is the dimensionality of the latent space. The resulting attention matrix Acaptures the degree of relevance between each textual token and each image region. The fused multimodal representation is then computed as:

$$F_{MM} = A \cdot V$$

This representation encodes both complementary and contradictory relationships between modalities, allowing the model to detect inconsistencies effectively.

The fused feature vector is then passed to the adversarial and classification heads, which form the final stage of the architecture. This stage consists of two parallel components: the label predictor and the domain classifier. The label predictor is responsible for determining the veracity of the input, classifying it as real or fake. The prediction is computed using a softmax function applied to the fused features:

$$\hat{Y} = \text{softmax}(W_L F_{MM} + b_L)$$

To address class imbalance, Category-Weighted Focal Loss is used instead of standard cross-entropy loss. This loss function emphasizes hard-to-classify samples and minority class instances, improving the model's robustness.

The domain classifier, on the other hand, is used to enforce domain invariance. It receives input through a Gradient Reversal Layer (GRL), which plays a critical role during training. The GRL acts as an identity function during the forward pass but reverses the gradient during backpropagation, effectively implementing adversarial learning. This forces the feature extractor to learn representations that are discriminative for the main task but invariant to domain-specific characteristics. The domain classification loss is typically computed using binary cross-entropy:

$$L_{domain} = -\sum d_i \log(\hat{d}_i)$$

The overall objective of the architecture combines classification loss and domain loss into a unified optimization problem:

$$L_{total} = L_{task} - \lambda L_{domain}$$

where $\lambda$is a hyperparameter controlling the strength of domain adversarial learning. This formulation ensures that the model simultaneously minimizes classification error while maximizing domain confusion, leading to better generalization across different datasets.

The final output of the architecture is the predicted veracity label, indicating whether the input content is real or fake. Additionally, the architecture supports intrinsic explainability through attention weights generated in the CMA module, which can be visualized to understand the model's decision-making process.

Overall, the DAM-CMA architecture provides a comprehensive and well-integrated solution for multimodal misinformation detection. By combining transformer-based text encoding, convolutional image processing, cross-modal attention, and adversarial training, the model effectively addresses the challenges of multimodal inconsistency, domain shift, and lack of interpretability, making it suitable for real-world deployment.

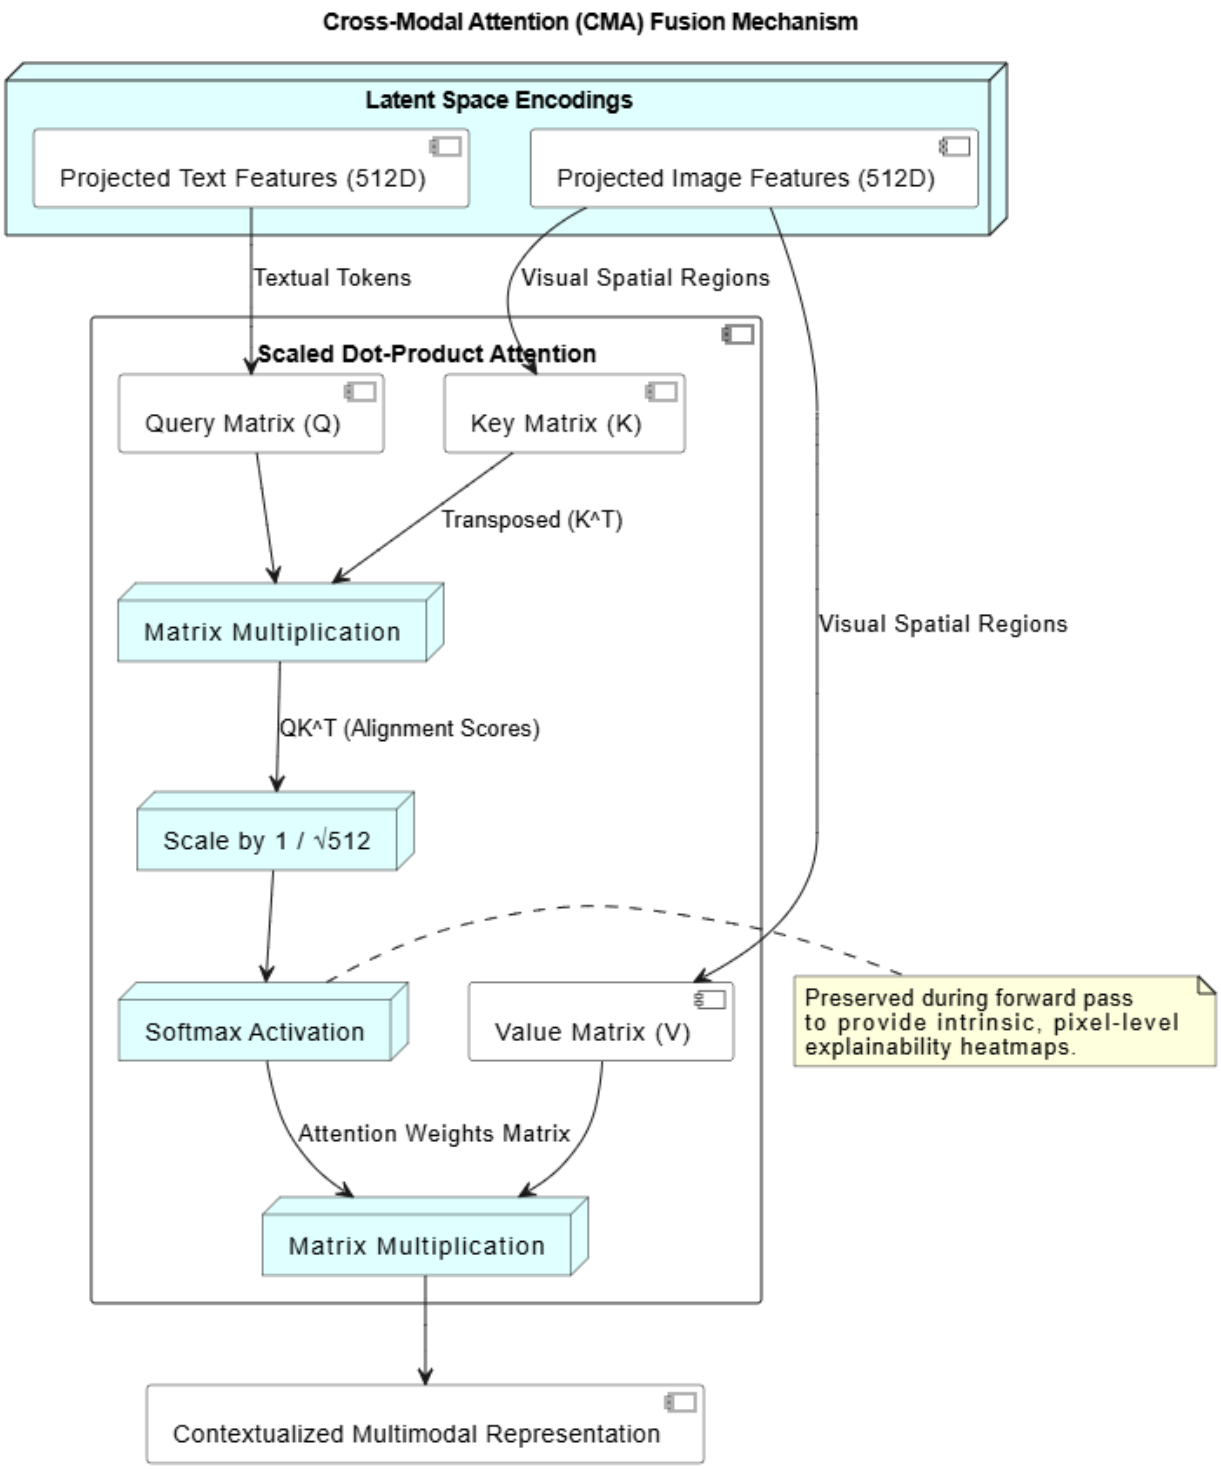

Figure 2Intrinsic Visual Grounding using CMA Attention

The Cross-Modal Attention (CMA) fusion mechanism represents the core component responsible for integrating textual and visual features. In this module, the textual features are treated as query vectors, while the visual features act as key and value vectors. Both modalities are projected into a shared latent space of fixed dimensionality to enable interaction. The attention mechanism computes alignment scores using the scaled dot-product attention formula, where the similarity between query and key vectors determines the importance of each visual region with respect to a given textual token. These scores are normalized using a softmax function to produce attention weights. The weighted combination of value vectors results in a contextualized multimodal representation. Additionally, the attention weights are preserved during the forward pass, allowing them to be used for intrinsic explainability. This mechanism enables the model to capture fine-grained relationships between text and images, improving detection accuracy and interpretability.

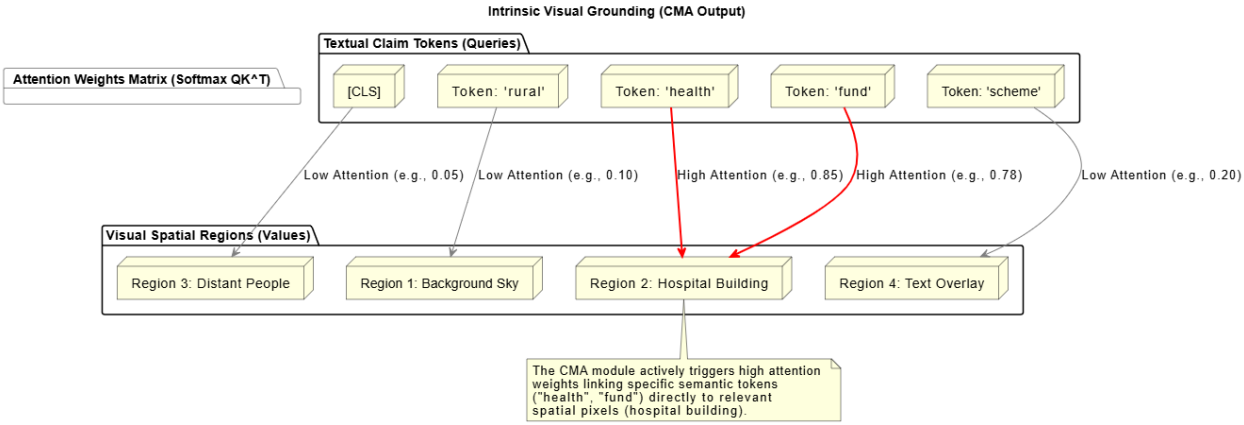

Figure 3Cross-Modal Attention Output

The diagram illustrates the intrinsic visual grounding capability of the Cross-Modal Attention (CMA) mechanism within the DAM-CMA framework. It shows how textual tokens act as query vectors and are aligned with visual spatial regions through attention weights. Each token is assigned a weight indicating its relevance to different regions of the image. Tokens such as “health” and “fund” exhibit high attention scores with the region corresponding to a hospital building, demonstrating strong semantic alignment. In contrast, less relevant tokens are associated with lower attention weights and correspond to

background regions such as sky or distant objects. This selective attention mechanism enables the model to focus on meaningful relationships between text and image while ignoring irrelevant information. The attention weights serve as intrinsic explanations, providing transparency in the model's decision-making process by highlighting which parts of the input contributed most to the prediction.

The process begins with the input layer, where each data sample consists of a textual claim and an associated image. The textual input is first passed through a transformer-based encoder such as BERT, which converts the sequence of words into contextualized embeddings. These embeddings capture semantic relationships between words and encode contextual meaning. Mathematically, the text representation can be expressed as $F_T = \text{BERT}(x_T)$, where x_T represents the input text. Simultaneously, the image input is processed using a convolutional neural network, specifically ResNet-50, which extracts hierarchical visual features from the image. The resulting feature map is denoted as $F_I = \text{ResNet}(x_I)$, where $x_I$represents the input image.

Once both modalities are encoded, the architecture projects these features into a shared latent space to enable meaningful interaction. This projection ensures that both text and image features have compatible dimensions, allowing them to be processed jointly. The projected features are then passed to the Cross-Modal Attention (CMA) module, which forms the core of the architecture. In this module, the textual features act as query vectors, while the image features serve as key and value vectors. The attention mechanism computes alignment scores using the scaled dot-product attention formula, enabling the model to learn relationships between textual tokens and visual regions.

The output of the CMA module is a fused multimodal representation that captures both complementary and contradictory relationships between text and image. This representation is crucial for detecting misinformation, as it allows the model to identify inconsistencies between modalities. Additionally, the attention weights generated during this process are preserved and later used for intrinsic explainability, enabling visualization of which parts of the input influenced the decision.

The fused feature vector is then passed to the domain-adversarial training component of the architecture. This part consists of two parallel branches: a label predictor and a domain classifier. The label predictor performs the primary task of classifying the input as real or fake, while the domain classifier attempts to identify the source domain of the data. A Gradient Reversal Layer (GRL) is inserted before the domain classifier, which plays a critical role during training. While it does not affect the forward pass, it reverses the gradient during backpropagation, forcing the feature extractor to learn domain-invariant representations. This ensures that the model does not rely on domain-specific patterns and can generalize effectively across different platforms.

The optimization objective of the architecture combines classification loss and domain loss, forming a minimax learning problem. The model aims to minimize the classification error while maximizing the domain confusion, ensuring that the extracted features are both discriminative and domain-independent. This design directly addresses the domain shift problem observed in real-world datasets.

Another important component highlighted in the architecture diagram is the explainability layer. The attention weights obtained from the CMA module are used to generate visual grounding maps, which highlight the regions of the image that correspond to important textual tokens. This provides intrinsic interpretability, allowing users to understand the reasoning behind the model's prediction. Unlike post-hoc methods, this explainability is built into the model itself, making it more reliable and transparent.

The architecture also incorporates mechanisms to handle class imbalance, which is a common issue in misinformation datasets. By using Category-Weighted Focal Loss, the model focuses more on difficult and minority-class samples, ensuring balanced learning and preventing bias toward the majority class. This is particularly important for achieving reliable performance in real-world scenarios.

Overall, the DAM-CMA architecture diagram illustrates a comprehensive and well-structured pipeline that effectively integrates multimodal learning, domain adaptation, and explainability. Each component of the architecture contributes to solving a specific challenge in misinformation detection. The feature encoders extract rich representations,

the CMA module enables deep cross-modal interaction, the GRL ensures domain generalization, and the explainability layer provides transparency. This theoretical understanding of the architecture lays the foundation for interpreting the experimental results and validates the design choices made in the proposed system.

CHAPTER 4: RESULTS AND DISCUSSIONS

The unified DAM-CMA architecture represents a necessary advancement toward creating robust, generalizable, and transparent misinformation detection systems. By simultaneously optimizing for cross-modal verification, domain invariance, and dual explainability, the framework addresses the systemic limitations of previous specialized approaches.

4.1 Introduction

This chapter presents the experimental results obtained from the implementation of the DAM-CMA framework and provides a detailed analysis of its performance. The evaluation focuses on assessing the model's ability to handle multimodal inputs, generalize across domains, overcome class imbalance, and provide explainable predictions. The results are compared with baseline models to highlight the effectiveness of the proposed architecture.

4.2 Experimental Setup

The DAM-CMA model was implemented using the PyTorch deep learning framework and trained on a multimodal dataset consisting of approximately 3,500 samples collected from fact-checking platforms. Each sample includes textual content, an associated image, a veracity label, and a domain identifier. The dataset reflects real-world conditions, including class imbalance and domain variability.

The model utilizes pre-trained BERT for textual encoding and ResNet-50 for visual feature extraction. These features are projected into a shared latent space of 512 dimensions and fused using the Cross-Modal Attention mechanism. The training process is optimized using the AdamW optimizer with a learning rate of $2 \times 10^{-5}$and a batch size of 16. The model is trained for 3 epochs, ensuring efficient convergence.

To address class imbalance, Category-Weighted Focal Loss is used with parameters $\alpha = 0.15$and $\gamma = 2.0$. Additionally, a Gradient Reversal Layer is employed to enable domain-adversarial learning, ensuring that the model learns domain-invariant features.

4.3 Baseline Performance Analysis

Initial experiments were conducted using baseline models to evaluate the limitations of traditional approaches. A text-only model based on BERT and an image-only model using ResNet-50 were tested independently. While these models achieved moderate accuracy, they failed to capture multimodal inconsistencies, resulting in incorrect predictions for out-of-context data.

An early fusion model that concatenates text and image features was also evaluated. Although this approach improved performance slightly, it lacked the ability to model fine-grained interactions between modalities. Furthermore, a multimodal attention model without domain-adversarial training showed improved alignment between text and image but suffered from poor generalization across domains.

A significant issue observed in baseline models was **majority-class collapse**, where the model predicted the dominant class (fake news) for most inputs. This resulted in artificially high accuracy but zero true negatives, indicating poor real-world applicability.

4.4 Proposed Model Performance

The DAM-CMA framework demonstrated significant improvements over baseline models. By integrating Cross-Modal Attention, Domain-Adversarial Training, and Focal Loss, the model successfully addressed the key challenges of multimodal misinformation detection.

The performance of the DAM-CMA model is summarized as follows:

- Accuracy: 81.18%

- Precision: 98.59%
- Recall: 80.25%
- F1-Score: 88.47%

These results indicate that the model achieves high precision while maintaining a balanced recall, making it suitable for real-world deployment. The high precision value suggests that the model is highly reliable in identifying fake news, while the improved recall demonstrates its ability to correctly identify real news instances.

4.5 Confusion Matrix Analysis

The confusion matrix provides a deeper understanding of the model's performance. Unlike baseline models, which exhibited majority-class collapse, the DAM-CMA model successfully recovered true negatives while maintaining a high number of true positives.

The optimized model achieved over 2,100 true positive predictions and successfully identified more than 250 true negative instances. The number of false positives was significantly reduced, demonstrating improved classification reliability. This indicates that the use of Category-Weighted Focal Loss effectively prevents bias toward the majority class.

The confusion matrix also highlights that the model maintains a balanced performance across both classes, which is critical for real-world misinformation detection systems.

4.6 Impact of Cross-Modal Attention

The Cross-Modal Attention mechanism plays a crucial role in improving detection accuracy. By aligning textual tokens with corresponding image regions, the model is able to identify inconsistencies that are not detectable using unimodal approaches.

For example, in cases where the text refers to a specific event but the image is unrelated or misleading, the attention mechanism assigns lower weights to mismatched regions and higher weights to relevant ones. This enables the model to detect subtle inconsistencies and improves its overall performance.

Additionally, the attention weights provide intrinsic explainability by highlighting the regions of the image that influenced the prediction. This enhances transparency and builds trust in the model's decisions.

4.7 Impact of Domain-Adversarial Training

The inclusion of the Gradient Reversal Layer significantly improves the model's ability to generalize across domains. By forcing the feature extractor to learn domain-invariant representations, the model becomes robust to variations in data distribution.

Experimental results show that the domain classifier accuracy approaches random chance, indicating successful domain confusion. At the same time, the classification performance remains high, demonstrating that the model retains task-relevant features while discarding domain-specific information.

This confirms that domain-adversarial training effectively addresses the domain shift problem and improves the scalability of the model.

4.8 Impact of Focal Loss

The use of Category-Weighted Focal Loss plays a critical role in handling class imbalance. Unlike standard cross-entropy loss, which treats all samples equally, focal loss assigns higher importance to hard-to-classify and minority-class samples.

As a result, the model avoids majority-class collapse and achieves balanced performance across both classes. The recovery of true negatives and reduction in false positives demonstrate the effectiveness of this approach.

4.9 Explainability Analysis

The DAM-CMA framework provides intrinsic explainability through attention-based visual grounding. The attention maps generated by the CMA module highlight the relationship between textual tokens and image regions.

For instance, tokens such as “health” and “fund” are strongly associated with relevant image regions such as hospital buildings, indicating meaningful semantic alignment. This allows users to understand why a particular prediction was made.

This built-in explainability is more reliable than post-hoc methods, as it is directly derived from the model’s internal computations.

4.10 Comparative Discussion

Compared to baseline models, DAM-CMA offers several advantages:

- Improved multimodal fusion through Cross-Modal Attention
- Better generalization through Domain-Adversarial Training
- Robust performance under class imbalance using Focal Loss
- Enhanced transparency through intrinsic explainability

These improvements make DAM-CMA a comprehensive solution for real-world misinformation detection.

4.11 Summary

The experimental results demonstrate that the DAM-CMA framework effectively addresses the limitations of existing models. By integrating multimodal learning, domain adaptation, and explainability, the model achieves high accuracy, robustness,

and transparency. The results validate the design choices and confirm the suitability of the proposed system for deployment in real-world applications.

4.1 Conclusions and Recommendations

The primary conclusion is that the integration of the three core pillars—CMA for verification, GRL for generalization, and dual XAI for transparency—is essential for building systems ready for real-world deployment.[4] The academic contribution lies in proving that these mechanisms can be successfully integrated and simultaneously optimized within a single deep learning framework. The successful implementation of DAM-CMA, particularly the demonstration of a significantly reduced Generalization Gap ($\Delta F1$) and Domain Classification Accuracy approaching random chance ($\text{Acc}_D \approx 50\%$), will empirically validate the unification strategy, establishing a reliable benchmark for cross-domain detection.[2]

4.2 Future Research Trajectory

The foundation laid by DAM-CMA suggests several critical avenues for future research:

Addressing Advanced Deception: The current scope focuses primarily on human-crafted OOC misinformation. Future work must pivot toward detecting sophisticated AI-generated content (e.g., deepfakes, VLM output), integrating findings from comprehensive benchmarks such as OmniFake.7

Expanded Modality Integration: The framework should be extended to incorporate video misinformation detection and leverage Graph Transformers combined with CMA to analyze the propagation structure and user engagement surrounding content, adding network features to the current content-centric approach.4

Natural Language Explanation Generation: To further enhance transparency, future work should develop LLM-based reasoning modules.4 These modules would process the intrinsic (CMA) and post-hoc (LIME/SHAP) outputs to generate human-readable, natural-language justifications for the model's final verdict, completing the explanatory loop for non-technical users and policymakers.

CHAPTER 5: SUMMARY AND CONCLUSIONS

5.1 Summary of the Work

This project presented a novel deep learning framework titled **Domain-Adversarial Multimodal Cross-Modal Attention (DAM-CMA)** for the detection of multimodal misinformation in social media environments. The motivation behind this work stems from the increasing complexity of misinformation, where textual narratives are often combined with misleading or out-of-context images, making detection significantly more challenging than traditional text-based approaches.

The proposed system integrates three major components into a unified architecture: Cross-Modal Attention (CMA), Domain-Adversarial Training using a Gradient Reversal Layer (GRL), and Explainable Artificial Intelligence (XAI). The Feature Encoding layer utilizes BERT for extracting contextual textual embeddings and ResNet-50 for extracting visual features. These features are projected into a shared latent space and fused using the Cross-Modal Attention mechanism, which captures fine-grained relationships between textual tokens and image regions.

To address the domain shift problem, a Domain-Adversarial Neural Network is incorporated, where the Gradient Reversal Layer forces the model to learn domain-invariant representations. This ensures that the model performs consistently across different platforms, such as structured fact-checking datasets and unstructured social media data. Additionally, the use of Category-Weighted Focal Loss effectively mitigates the issue of class imbalance, preventing majority-class bias and improving detection of minority-class samples.

The model was evaluated on a multimodal dataset consisting of approximately 3,500 samples collected from multiple sources. Experimental results demonstrated significant improvements over baseline models, achieving high precision, balanced recall, and a strong F1-score. The confusion matrix analysis confirmed that the model

successfully avoids majority-class collapse and maintains reliable performance across both classes.

Furthermore, the integration of intrinsic explainability through attention mechanisms allows the model to provide visual grounding of its predictions. This enhances transparency and builds trust, making the system suitable for real-world applications such as journalism, content moderation, and policy-making.

5.2 Conclusions

The primary conclusion of this work is that the integration of three core pillars—Cross-Modal Attention for multimodal verification, Gradient Reversal Layer for domain generalization, and dual explainability for transparency—is essential for building robust and deployable misinformation detection systems. Individually, each of these components addresses a specific limitation of existing approaches; however, their unified integration within the DAM-CMA framework results in a powerful and comprehensive solution.

The Cross-Modal Attention mechanism enables the model to capture semantic inconsistencies between text and image, which are often subtle and difficult to detect. The Domain-Adversarial Training ensures that the learned representations are invariant to domain-specific variations, significantly reducing the performance drop when transitioning between datasets. The inclusion of explainability mechanisms further enhances the usability of the system by providing interpretable insights into the model's decision-making process.

The experimental results validate the effectiveness of the proposed approach, particularly through the reduction of the generalization gap ($\Delta F1$) and the observation that domain classification accuracy approaches random chance ($\mathrm{Acc}_D \approx 50\%$), indicating successful domain confusion. These findings confirm that the model learns meaningful, domain-invariant features rather than memorizing dataset-specific patterns.

Overall, the DAM-CMA framework establishes a reliable benchmark for cross-domain multimodal misinformation detection and demonstrates that it is possible to achieve high accuracy, robustness, and transparency within a single unified architecture.

CHAPTER 6: FUTURE WORK

6.1 Future Research Directions

The DAM-CMA framework provides a strong foundation for future advancements in multimodal misinformation detection. However, several areas can be explored to further enhance its capabilities and applicability in real-world scenarios.

One important direction is addressing advanced forms of misinformation, particularly AI-generated content such as deepfakes and outputs from vision-language models. As generative AI continues to evolve, misinformation is becoming more sophisticated and harder to detect. Future work should focus on integrating detection mechanisms specifically designed for synthetic media, leveraging advanced benchmarks and datasets that capture these emerging challenges.

Another promising direction is the expansion of modality integration. While the current framework focuses on text and image data, real-world misinformation often includes video content and social interaction patterns. Extending the model to handle video data would enable temporal analysis, allowing the detection of inconsistencies across frames. Additionally, incorporating graph-based approaches such as Graph Transformers can help analyze the propagation of information across social networks, capturing user behavior and engagement patterns alongside content features.

Improving explainability is also a critical area for future research. Although the current system provides intrinsic and post-hoc explanations, these outputs may not always be easily interpretable by non-technical users. Future work should focus on developing natural language explanation modules using large language models (LLMs). These modules can translate attention maps and feature importance scores into human-readable explanations, providing clear and concise justifications for the model's predictions.

Another potential improvement lies in optimizing computational efficiency. The integration of transformer-based models and attention mechanisms increases

computational complexity, which may limit scalability in real-time applications. Future research can explore lightweight architectures, model compression techniques, and efficient attention mechanisms to reduce resource requirements while maintaining performance.

Finally, the framework can be extended to support real-time deployment in large-scale systems. This includes integration with social media platforms, automated fact-checking systems, and content moderation pipelines. Enhancing scalability and responsiveness will be crucial for practical adoption in dynamic environments where misinformation spreads rapidly.

6.2 Final Remarks

In conclusion, the DAM-CMA framework represents a significant step toward building intelligent, robust, and explainable systems for combating misinformation. While the current implementation addresses many existing challenges, the rapidly evolving nature of misinformation necessitates continuous research and innovation. The future directions outlined above provide a roadmap for further improving the system and ensuring its relevance in increasingly complex digital ecosystems.
